ABSTRACT
The aim of the present study was to elucidate the possible biochemical changes in lipid metabolism and organ function after treatment with sildenafil in normal and hyperlipidemic albino rats. Albino rats were grouped into seven groups (n=10/group) with blood sampling on days 30, 45 and 60 of the experiment for biochemical analysis. Group-i and -ii were fed on normal and cholesterol (1%) and fat (2%)-enriched diets, respectively. Group-iii and -iv were fed on normal and cholesterol (1%) and fat (2%)-enriched diets, respectively received sildenafil (5.625 mg/kg b. wt., orally, daily) after 30 days from the start of the experiment. Group-v received same diet like group-ii and treated with sildenafil at the start of the experiment. Group-vi and -vii were fed same diet like group-ii but received atorvastatin (1.8 mg/kg b.wt, orally, daily) and ezetimibe (1 mg/kg b.wt.), respectively after 30 days from the start of the experiment. Sildenafil significantly decreased the serum lipid parameters in hyperlipidemic rats, but increased these values in negative control rats. Sildenafil caused a significant decrease in serum liver enzymes (ALT and AST), urea and creatinine in animals fed on fat- and cholesterol-enriched diet compared to the positive untreated ones. Concurrent administration of sildenafil with high fat and cholesterol diet (group-iv) failed to guard against the rise in liver and kidney function biomarkers. These data suggest that sildenafil may act as a mixed blessing drug; therefore it must be used carefully and under physician supervision to get its therapeutic benefits and guard against its adverse effects.

KEY WORDS: Cholesterol, Hyperlipidemia, Lipid, Rat, Sildenafil.

1. INTRODUCTION
Erectile dysfunction (ED) is the persistent inability to achieve and maintain an erection adequate for satisfactory sexual performance. The probability of erectile dysfunction increases with age and the presence of some disease conditions such as diabetes mellitus, hypertension, hypercholesterolemia, ischemic cardiac disease, depression and obesity [28]. The pharmaceutical preparation sildenafil citrate (Viagra®) is being widely prescribed as a treatment for male ED [20]. Sildenafil belongs to a class of compounds called phosphodiesterase (PDE) inhibitors. PDEs comprise a diverse family of enzymes that hydrolyze cyclic nucleotides, cyclic adenosine-5-monophosphate and cyclic guanosine-5-monophosphate (cAMP and cGMP) and therefore play a critical role in the modulation of second messenger signaling pathways [6].

Corresponding author: A. El Mahmoudy, Ass. Prof. of pharmacology, e-mail: elmahmoudy@hotmail.com. Fax: +2013-2463074
Sildenafil is a potent and selective inhibitor of PDE-5, the predominant isozyme that metabolizes cGMP in the corpus cavernosum of the penis. cGMP is the second messenger of nitric oxide (NO) and a principal mediator of smooth muscle relaxation and vasodilatation in the penis. By inhibiting the hydrolytic breakdown of cGMP, sildenafil prolongs the action of cGMP. This may be attributed to the augmented smooth muscle relaxation and hence, prolongation of the erection [27, 31].

However, the selectivity of sildenafil for PDE-5 has not been completely understood and may be partially lost upon sildenafil abuse. In addition, it is unclear that the enhancement of intracellular cGMP concentration does not generate major unwanted biological effects in tissues other than corpus cavernosum especially those related to lipid metabolism and vital organ functions. Therefore, the aim of the present study was to elucidate the possible biochemical alterations in lipid metabolic profile and organ function profiles that may result from continuous treatment with sildenafil in normal albino rats and those rendered hyperlipidemic by long term supplementation of fat and cholesterol-enriched diet.

2. MATERIALS AND METHODS

**Sildenafil**
Sildenafil was provided as sildenafil citrate which is a white to off-white crystalline powder of a molecular weight of 666.7. It is present in the drug market as the patent preparation Viagra® that is an oral therapy for ED, formulated as blue, film-coated rounded-diamond-shaped tablets equivalent to 25 mg, 50 mg and 100 mg of sildenafil for oral administration. However, in the present study, it was obtained as a kind gift from SIGMA Pharmaceutical Co., Quesna, Egypt, in its powder form. The dosage range for human is 25~100 mg/day, orally, according to the severity of the condition. The average dose prescribed for human (62.5 mg/day) was converted to equivalent dose for rat according to Paget and Barnes [29]. The rat dose was calculated as 5.625 mg/kg B Wt. Thus, a rat weighing 200 g received a daily dose of 1.125 mg suspended in 0.5 ml distilled water orally using a gastric tube of suitable size.

![Chemical structure of sildenafil citrate](image)

**Atorvastatin**
Atorvastatin (an inhibitor of cholesterol synthesis) used in the present study was produced by E.P.I.C.O (Egyptian Pharmaceutical International Company), 10th of Ramadan City, Egypt, under the commercial name ATOR®. It is presented as tablets containing 10, 20 and 40 mg of the drug. Atorvastatin was suspended in distilled water (0.66 mg/ml; 10mg tablet in 15 ml) and each rat was administered 0.5 ml of the prepared suspension daily using a gastric tube. This amount is equivalent to the dosage rate of 1.8 mg/kg B Wt. daily (converted from human dose after Paget and Barnes [29] to the corresponding groups explained later.

**Ezetimibe**
EZE (an inhibitor of cholesterol absorption) used in the present study was a kind gift from SIGMA pharmaceuticals, Quesna, Egypt. It was obtained as a pure powder. EZE was dissolved in 20% ethanol; where 10 mg of EZE were dissolved firstly in 5 ml absolute alcohol, and then the alcoholic EZE solution was completed to 25 ml by distilled water. Each rat within the target group received
0.5 ml of the prepared solution which is equivalent to a dosage rate of 1 mg/kg BWt., orally, once daily [30].

Experimental animals
Seventy albino rats of both sexes aging 6-8 weeks of approximate weights 180-210 g were used in this study. Rats were kept in separate cages and allowed to a plenty of water and diets at room temperature. After one week of acclimatization, rats received different treatments as follows:

GROUP I: Rats were fed on normal diet and received no drugs; kept as negative control.

GROUP II: Rats were fed on cholesterol and fat-enriched diet and received no drugs; kept as positive control for all experimental groups.

GROUP III: Rats were fed on normal diet and received ice sildenafil after 30 days from the start of the experiment; kept as negative treated group.

GROUP IV: Rats were fed on cholesterol and fat-enriched diet and received ice sildenafil after 30 days from the start of the experiment; kept as positive treated group.

GROUP V: Rats were fed on cholesterol and fat-enriched diet and received sildenafil from the start of the experiment; kept as concurrent treatment group.

GROUP VI: Rats were fed on cholesterol and fat-enriched diet and received atorvastatin after 30 days from the start of the experiment; kept as a standard treated group.

GROUP VII: Rats were fed on cholesterol and fat-enriched diet and received EZE after 30 days from the start of the experiment; kept as standard treated group.

Sampling
Blood for serum was collected on the 30th, 45th and 60th days from the start of the experiment. Samples were collected from the venous plexus located at the medial canthus of the eye by means of heparinized capillary tubes. The collected blood was allowed to clot at room temperature for an hour; and then refrigerated for further an hour for clot retraction. Clear sera were separated by centrifugation at 3000 r.p.m. for 10 minutes and then collected in Eppendorf’s tubes using automatic pipettes. Serum samples were kept in deep freezer (-20 °C) for analysis of the following biochemical parameters:

- Total lipids (TL),
- total cholesterol (TC),
- triglycerides,
- high density lipoprotein-cholesterol (HDL-C),
- low density lipoprotein-cholesterol (LDL-C),
- very low density lipoprotein-cholesterol (VLDL-C),
- aspartate amino transferase (AST; SGOT),
- alanine amino transferase (ALT; SGPT),
- urea and creatinine.

Biochemical analysis
The serum total lipids were determined according to the method described by Chabrol [9] using a kit supplied by SPINREACT, Sant Esteve De Bas, Spain; total cholesterol was determined enzymatically according to the method described by Meiattini [23] using a kit supplied by SPINREACT; HDL-C was determined according to the precipitation method described by Friedewald et al., [15] using a kit supplied by SPECTRUM, Obour city, Egypt; triglycerides were determined enzymatically according to the method described by Young and Pestaner [37] using a kit SPINREACT. LDL-C and VLDL-C values were calculated using the formulae described by Friedewald et al., [15] and Bauer [5], respectively. Serum AST and ALT were quantitatively determined according to the method described by Murray [24] using kits supplied by DIAMOND, Cairo, Egypt. Urea was quantitatively determined according to the method described by Kaplan [19] using a kit supplied by DIAMOND, Cairo, Egypt; while creatinine was quantitatively determined according to the method described by Murray [24] using a kit supplied by the same company.

Statistical analysis
Data were expressed as mean ± S.E which are calculated using SigmaPlot® software. The obtained data were statistically analyzed using Student's t-test to express the differences between groups according to Snedecor and Cokran [34].

3. RESULTS

3.1. Effect of sildenafil on serum total lipids

As shown in table 1, there was a significant increase in serum total lipid concentration in rats fed on fat- and cholesterol-enriched diet, compared to rats received basal diet. While administration of sildenafil suspension to normal rats caused significant rise in serum total cholesterol concentration on the days 45 and 60 of the experiment if compared with the negative control rats; yet, it significantly decreased serum total lipid concentration in animals fed on fat- and cholesterol-enriched diet compared to the positive untreated ones, on the same days. Administration of sildenafil from the start of the experiment along with fat- and cholesterol-enriched diet failed to impede induction of hyperlipidemia in the concerned rats. However, the level of serum total lipid was a midway between –ve and positive groups with significance (P<0.05) against –ve group and without significance against positive group.

3.2. Effect of sildenafil on serum cholesterol:

As shown in table 2, there was a significant increase in serum cholesterol concentration in rats fed on fat- and cholesterol-enriched diet, compared to rats received basal diet. Daily oral administration of sildenafil significantly decreased serum cholesterol concentration in animals fed on fat- and cholesterol-enriched diet compared to the positive untreated ones. However, it significantly increased TG concentration in animals kept on basal diet when fed from the day 30 (group 3) or from the start of the experiment (group 5).

3.3. Effect of sildenafil on serum triglycerides

As shown in table 3 there was a significant increase in TG concentration in rats fed on fat- and cholesterol-enriched diet, compared to rats received basal diet. Daily oral administration of sildenafil significantly decreased serum TG concentration in animals fed on fat- and cholesterol-enriched diet compared to the positive untreated ones. However, it significantly increased TG concentration in animals kept on basal diet when fed from the day 30 (group 3) or from the start of the experiment (group 5).
Sildenafil effect on experimental hyperlipidemia.

3.4. Effect of sildenafil on serum lipoproteins

As shown in tables 4, 5, and 6 revealed significant increases in serum LDL-C and VLDL-C and a significant decrease in HDL-C in the group of rats that was fed on fat- and cholesterol-enriched diet all over the period of the experiment, compared to the corresponding control group.

Analysis of samples taken on the days 30, 45 and 60 in the present study, have shown that sildenafil administration revealed significant changes in serum lipoproteins in rats fed on both basal and high-fat diets. It caused significant decreases in LDL-C and VLDL-C concentrations and a significant increase in HDL-C if compared to the rats which were fed fat- and cholesterol-enriched diet. On the other hand, it produced reverse actions when administered to rats fed on basal diet.

3.5. Effect of sildenafil on Liver function profile

Data of the present study (tables 7 and 8) demonstrate a significant increase in serum ALT and AST concentrations of rats fed on fat- and cholesterol-enriched diet all over the two-month period of the experiment, compared to the control rats that received basal diet. Although administration of sildenafil to normal rats caused insignificant changes in serum liver enzymes concentration all over the period of the experiment; yet, it significantly decreased their serum concentrations in animals fed on fat- and cholesterol-enriched diet compared to the positive untreated ones, upon its administration starting from the day 30th of the experiment. However, concurrent administration of sildenafil with high fat and cholesterol diet failed to guard against the rise in liver enzymes.
Table 9: Effect of sildenafil on serum urea: Effect of oral administration of 0.5 ml sildenafil suspension (equivalent to 25 mg/kg b. wt) daily on serum urea concentration.

![Table 9](image)

Although administration of sildenafil to normal rats caused insignificant changes in serum urea and creatinine concentrations all over the period of the experiment; yet, it significantly decreased their serum concentration in animals fed on fat- and cholesterol-enriched diet compared to the positive untreated ones, upon its administration starting from the day 30th of the experiment. However, concurrent administration of sildenafil with high fat and cholesterol diet failed to guard against the rise of serum urea and creatinine.

### 4. DISCUSSION

Historically, the story starts when coffee was discovered about 2000 years ago by goat herders in Ethiopia. Caffeine was found to be the main active ingredient in coffee in 1960. Caffeine produced various biological actions on different body systems. The first discovered mechanism of these actions was phosphodiesterase (PDE) inhibition. This fact does not exclude that caffeine has effects on other non-PDE. From this little far beginning, it could be stated that caffeine was the first known PDE inhibitor [12]. Later on, it was shown that at least 15 PDE isoenzymes exist, and that caffeine inhibits most of them and thus acts as non-selective PDE inhibitor. Major research efforts have led to the production and development of compounds that are more selective and more potent in inhibiting particular PDEs [11].

Sildenafil (Viagra) (figure 1) is the first commercialized compound in this class, which selectively inhibits PDE-5 that is present mainly in the corpus cavernosum of the penis. This has been followed by introduction of more or less similar drugs, including vardenafil (Levitra) and tadafalil (Cialis). Vardenafil has a similar structure as sildenafil, but tadafalil
structure is different. Part of the ring structure of sildenafil or vardenafil is similar to that of caffeine.

The ring structure in sildenafil and vardenafil is similar to a ring structure in cyclic guanosine monophosphate (cGMP) giving the scientific basis of these drugs to be competitive inhibitors of cGMP for PDE-5. Inspite of the different structure of tadalafil, yet, its molecular mechanism of action is believed to be similar.

The normal pathway for penile erection is illustrated in figure 2. If the cGMP level in corpus cavernosum smooth muscle cells is not elevated sufficiently or if relaxation of smooth muscle in this tissue is deficient due to cholesterol deposition or hyperlipidemia, a condition of erectile dysfunction (ED) revealed [10, 18].

PDE-5 inhibitors enhance erectile function during sexual stimulation by penetrating into smooth muscle cells and inhibiting PDE-5. This results in decreased degradation of cGMP, which maintains sufficient cellular levels of cGMP in both corpus cavernosum and the vessels supplying it. This increases relaxation of the smooth muscle, which dilates the corporeal sinusoids resulting in increased blood flow, allowing an erection to occur.

cGMP is the second messenger for nitric oxide (NO) that is released, upon sexual stimulation, from non-adrenergic, non-cholinergic neurons (NANC) supplying the penile tissue. PDE-5 inhibitors do not increase the NO level, but they potentiate it.

The vast use of PDE-5 inhibitors in ED which is usually associated with diabetic, cardiovascular and other metabolic abnormalities, leads the researchers to investigate their possible extra-sexual effects, and the present study is among them. Other stimuli to do this research are recent animal studies that highlighted a possible interaction between chronic PDE-5 inhibition and glucose homeostasis which occurs through a marked improvement of high fat diet induced insulin resistance. In addition, it is unclear that the enhancement of intracellular cGMP concentration does not generate major unwanted biological effects in tissues other than corpus cavernosum especially those related to lipid metabolism and vital organ functions.

Data of the present study revealed that continuous administration of sildenafil affected lipid metabolic profile and organ function of both normal and hyperlipidemic rats in a complex manner that needs further studies to be completely understood. Hyperlipidemia rat model was used to simulate more or less the health profile of most of ED patients, as the two conditions are closely related and interactive [22].

In the present study, hyperlipidemia, induced by continuous supplementation of high fat (coconut oil 2% wt/wt) and high cholesterol diet (1% wt/wt), caused marked alterations (mainly increase except HDL-C which is decreased) in almost all lipid parameters of rat groups fed on such diet. Moreover, the obtained hyperlipidemia was associated with elevated markers for some organ dysfunction as liver, kidneys and aorta together with considerable histopathological changes in these organs (data not shown). These findings led us to use such rats as a model for hyperlipidemia to assess the possible modulating role of sildenafil that is used on a large scale either with physician prescription or, more dangerously, without prescription even in youth as a personal thinking of improving their sexual performance.

Data of the present study (table 1) demonstrate a significant increase in serum total lipid concentration of rats fed on fat- and cholesterol-enriched diet all-over the two-month period of the experiment, compared to the control rats that received basal diet. This result of hyperlipidemia is consistent to that have been reported previously in more than one species including, rats by Csont et al. [13], rabbits
by Diaz et al. [14] and Hellal [17] and laying hens by Attia [3]. Data of the present study (table 2) demonstrate a significant increase in serum total cholesterol concentration of rats fed on fat- and cholesterol-enriched diet all over the two-month period of the experiment, compared to the control rats that received basal diet. This result is consistent with those achieved by by Diaz et al [14] who reported that, rabbits fed with the atherogenic diet showed marked increase in plasma total cholesterol. The result is also consistent with that of Abdel-Maksod et al. [1] who reported that mice and rats received cholesterol-enriched diet showed sever hypercholesterolemia, elevated plasma serum LDL-C and VLDL-C compared to those fed a normal diet. In addition, Attia [3] reported that, administration of laying hens with diet rich in cholesterol diet led to marked elevation in plasma total cholesterol. Rise in serum cholesterol might be attributed to the reduced catabolic rate of serum TC or reduced activity of hepatic cholesterol-7-alpha-hydroxylase, the rate limiting enzyme in bile acid synthesis from cholesterol Abdel-Maksod et al. [1]. Moreover, the rise in serum TC observed in this study could be attributed to increased HMG-CoA reductase activity in the liver of animals fed on fat- and cholesterol-enriched diet and the reduced rate of the clearance of LDL from circulation due to defective LDL receptors which associated with increase of plasma TC concentration [38]. Similarly, Yoshie et al. [35] stated that rabbits with high serum cholesterol concentrations developed intimal lesions similar to those of human atherosclerosis. Although administration of sildenafil suspension to normal rats caused significant rise in serum total cholesterol concentration on the days 45 and 60 of the experiment if compared with the negative control rats; yet, it significantly decreased serum cholesterol concentration in animals fed on fat- and cholesterol-enriched diet compared to the positive untreated ones, on the same days. Administration of sildenafil from the start of the experiment along with fat- and cholesterol-enriched diet failed to stop induction of hypercholesterolemia in the concerned rats. However, the level of cholesterol was a midway between negative and positive groups with significance (P<0.05) against negative group and without significance against positive group. This data may be consistent with Sivasankaran et al. [33] who found that the long term combined administration of single daily doses of sildenafil plus ethanol increased serum cholesterol compared to control rats. Testicular tissue cholesterol was found also to be increased. In our study, sildenafil behavior was atorvastatin-like rather than ezetimibe which are the standard antihyperlipidemic drugs used in this experiment. The hypocholesterolemic effect of sildenafil in high-cholesterol group, therefore, may be explained on the basis of increasing the transfer of blood cholesterol to be used in bile synthesis and thus, biliary excretion of cholesterol or bile acids is increased resulting in reduced availability of cholesterol to be incorporated into lipoproteins [2]; not on the basis of decreased cholesterol absorption inhibition. A speculation that cGMP might be related to enhanced cholesterol metabolism cannot be excluded. Modulation of cholesterol concentration by sildenafil was assumed to be the reason of ameliorating the aortic degenerative atherosclerotic-like lesions in sildenafil-treated rats. Data of the present study demonstrated in table 3 showed a significant increase in triglycerides in animals kept on fat- and cholesterol-enriched diet compared to their corresponding control. This result may be in accordance with those recorded by Brousseau et al. [8], who found that a hyperlipidemic diet caused a significant increase of the plasma triacylglycerols and an increased content of cholesterol in the liver, despite the fact that the diet
Sildenafil effect on experimental hyperlipidemia.

produced a cessation of endogenous cholesterol synthesis. Such significant rise in serum triacylglycerols level may be attributed to the decrease of activity of lipase which is an insulin-dependent enzyme involved in triglyceride clearance from plasma by mediating triglyceride lipolysis into glycerol and FFA [36]. Another possibility is that such significant increase in triglycerides might be a consequence of over production of VLDL by the liver.

Daily oral administration of sildenafil significantly decreased serum TG concentration in animals fed on fat- and cholesterol-enriched diet compared to the positive untreated ones. However, it significantly increased TG concentration in animals kept on basal diet when fed from the day 30 (group 3) or from the start of the experiment (group 5). This data may be consistent with that of Sivasankaran et al. [33] who found that the long term combined administration of single daily doses of sildenafil plus ethanol increased serum triglycerides time-dependently along 45 days, compared to control rats. Testicular tissue triglyceride level was found also to be increased.

The significant decrease in plasma TG was explained previously by Bennani-Kabchi et al. [7] who related them to the increased rate of lipolysis that is mediated by increase of plasma lipase activity. However, Griffin et al. [16] stated that the low plasma TG concentration might also reflect the low rate of hepatic lipogenesis or the use of plasma TG by tissues other than adipose ones.

Data obtained in the present study that demonstrated in tables 4, 5 and 6 revealed significant increases in serum LDL-C and VLDL-C and a significant decrease in HDL-C in the group of rats that was fed on fat- and cholesterol-enriched diet all over the period of the experiment, compared to the corresponding control group.

These results are in accordance with those reported by Abdel-Maksod et al. [1], who reported that mice and rats receiving cholesterol-enriched diet showed sever elevated plasma LDL-C and VLDL-C compared to those kept on a normal diet. Hussein and colleagues concluded that the elevated serum LDL-C and VLDL-C seemed to be related mainly to reduced catabolic rate that occurs when the production of LDL exceeds the capacity of LDL receptors present on hepatocytes; in other words when the efflux of cholesterol from the liver becomes more than its influx. Mahley and Holcombe [21] added that both dietary fat and cholesterol may change the lipoprotein content of serum and affect the different classes of lipoproteins, LDL and HDL and increases the content of cholesterol in VLDL.

Analysis of samples taken on the days 30, 45 and 60 in the present study, have shown that sildenafil administration revealed significant changes in serum lipoproteins in rats fed on both basal and high-fat diets. It caused significant decreases in LDL-C and VLDL-C concentrations and a significant increase in HDL-C in compared to the rats which were fed fat- and cholesterol-enriched diet. On the other hand, it produced reverse actions when administered to rats fed on basal diet. The improving effect of sildenafil may be explained by what was reported by Ayala et al. [4] that chronic sildenafil administration (12 weeks) counteracted the detrimental effects of a high-fat diet on endothelial function and insulin resistance by improving insulin function and energy balance. They added that effect persisted even in the presence of NO donors, suggesting direct effects of sildenafil on metabolism other than eNOS activation. Improving insulin function may increase lipoprotein lipase activity with the result of observed effects of sildenafil. The increasing effect of sildenafil in normal rats that were fed on basal diet remains to be understood.

Additional mechanisms of the improving effect on lipoproteins that may be applied on sildenafil, may be, probably, decreasing the apoB which is the principal protein that
comprises nearly 90% of total protein mass of LDL as stated by Ramadan et al. [32]. In addition, it may be speculated that sildenafil may increase the peripheral and hepatic breakdown of cholesterol esters from VLDL and LDL. While the compositional change of HDL also suggests activation of Lecithin-cholesterol acyl transferase (LCAT) which must be stimulated firstly by exogenous cholesterol.

Data of the present study (tables 7 and 8) demonstrate a significant increase in serum ALT and AST concentrations of rats fed on fat- and cholesterol-enriched diet all-over the two-month period of the experiment, compared to the control rats that received basal diet. Although administration of sildenafil to normal rats caused insignificant changes in serum liver enzymes concentration all over the period of the experiment; yet, it significantly decreased their serum concentrations in animals fed on fat- and cholesterol-enriched diet compared to the positive untreated ones, upon its administration starting from the day 30th of the experiment. However, concurrent administration of sildenafil with high fat and cholesterol diet failed to guard against the rise in liver enzymes. These data may be explained on the basis of decreased ability of the diseased liver to metabolize sildenafil by hepatic microsomal cytochrome P450 which may result in increased efficacy of sildenafil with increasing its dose; while in normal rats the full metabolizing effect of their healthy liver may mask the effect of sildenafil. However, further studies are still needed for more understanding such discrepancy.

As for renal function tests, sildenafil treatment decreased significantly serum urea and creatinine concentrations which were elevated upon continuous high cholesterol diet (tables 9 and 10; p<0.05). Such rise might be attributed to the nephritic changes occurred in the renal tissue upon cholesterol administration (histopathological finding not shown).

These changes might be mildened upon sildenafil administration due its cholesterol lowering and renal artery dilating effects. These data suggest that sildenafil may act as a mixed blessing drug; therefore it must be used carefully and under physician supervision to get its therapeutic benefits and guard against its adverse effects.

الملخص العربي

هدف الدراسة الحالية إلى توضيح التحويلات البيوكيميائية المحتملة في جانب أضف الدهون وجانب وظائف الأعضاء والتي قد تنتج عن المعالجة المستمرة بعقار السلدنافيل للفئران البيضاء الصحية وتلك التي تتميز بزيادة نسبة الدهون في دمها عن طريق تغذيتها على مدى طويل بعلبة غنية بالدهون وموضأا إياها الكوليسترول. وقد أوضحت النتائج أن عقار السلدنافيل أدى إلى حدوث نقص معنوي في تركيز الدهون الكلية ممثلا في الكوليسترول والجلسريدات الثلاثية في كل الدم الخاص بالفئران التي تغذت على علبة غنية بالدهون وموضأا إياها الكوليسترول، ولكنه بشكل غير متوقع أدى إلى زيادة في تركيز الدهون الكلية في كل الدم الخاص بالفئران المجموعة الضابطة السلبية، كما أنه أدى إلى حدوث تغيرات معنوية في تركيز البروتينات الدهنية في كل الدم الخاص بالفئران التي تغذت على علبة أساسية أو غنية بالدهون حيث أدى إلى حدوث نقص معنوي في تركيز البروتينات الدهنية منخفضة الكثافة وشديدة إنخفاض الكثافة وأدى إلى حدوث زيادة معنوية في تركيز البروتينات الدهنية عالية الكثافة إذا ما قرنى تلك الفئران التي تغذت على علبة غنية بالدهون وموضأا إياها الكوليسترول، ولكن لاحظ حدوث تأثير عكسي في كل الدن الخاصة بالفئران المجموعة الضابطة السلبية، وبالرغم من أن تجريع السلدنافيل لم تؤدي إلى تغيرات معنوية في تركيز الإنزيمات الدالة على نشاط الكبد، ALT، AST، وكذلك المؤثرات الدالة على نشاط الكلي، الديدار والكلاهينين، في مصل الدم الخاص بالفئران المجموعة الضابطة، طول فترة التجربة؛ رغم ذلك، فإنه أدى إلى نقص معنوي بتركيزهم في مصل الدم الخاص بالفئران التي تغذت على علبة غنية بالدهون وموضأا إياها الكوليسترول مقارنة بالفئران المجموعة الضابطة الإيجابية، مع تجريعه بدء من اليوم الثلاثون للتجربة. وكذا، تجرع المتزامن للسلايدافيل مع علبة غنية بالدهون وموضأا إياها الكوليسترول أخذ في الحماية من ارتفاع تلك الإنزيمات. أوضحت هذه البيانات بأن السلدنافيل قد يعمل كعقار ذو متاعبة وضرر؛ لذا فيجب أن يستعمل بعناية وتحت إشراف الطبيب للحصول على منافعه العلاجية وتجنب من تأثيراته الضارة.
